Abstract

**Background** Clinical workplace-based learning has been the means to becoming a medical professional for many years. The importance of an adequate patient mix, as defined by the number of patients and the types of medical problems, for an optimal learning process is based on educational theory, and recognized by national and international accreditation standards. The relationship between patient mix and learning in work-based curricula as yet remains unclear.

**Aim** To review research addressing the relationship between patient mix and learning in work-based clinical settings.

**Method** The search was conducted across Medline, Embase, Web of Science, ERIC and the Cochrane Library from the start date of the database to July 2011. Original quantitative studies on the relationship between patient mix and learning for learners at any level of the formal medical training/career were included. Methodological quality was assessed and two reviewers using pre-specified forms extracted results.

**Results** A total of 10,420 studies were screened on title and abstract. Of these, 298 articles were included for full-text analysis, which resulted in the inclusion of 22 papers. The quality of the included studies, scored with the Medical Education Research Study Quality Instrument (MERSQI), ranged from 8.0 to 14.5 (out of 18 points). A positive relationship was found between patient mix and self-reported outcomes evaluating the progress in competence as experienced by the trainee, such as self-confidence and comfort level. Patient mix was also found to correlate positively with self-reported outcomes evaluating the quality of the learning period, such as self-reported learning benefit, experienced effectiveness of the rotation, or the instructional quality. Variables, such as supervision and learning style, might mediate this relationship. A relationship between patient mix and formal assessment has never been demonstrated.

**Conclusion** Patient mix is positively related to self-reported learning outcome, most evidently the experienced quality of the learning programme.
Introduction
Clinical workplace-based learning has played the leading role in educating medical professionals for many years. The importance of an adequate case or patient mix at that workplace for an optimal learning process is intuitively felt by many professionals and is recognized by several national (Australian Medical Council Limited, 11 A.D.; Liaison Committee on Medical Education (LCME), 2011; Royal College of General Practitioners, 2011) and international accreditation standards; the World Federation for Medical Education emphasized this in its Global Standards for Quality Improvement, for Postgraduate Medical Education (Karle, 2010). It states 'Training locations must have a sufficient number of patients and an appropriate case-mix to meet training objectives. The training must expose the trainee to a broad range of experience in the chosen field of medicine and, when relevant, include both inpatient and outpatient (ambulatory) care and on-duty activity. The number of patients and the case-mix should allow for clinical experience in all aspects of the chosen specialty, including training in promotion of health and prevention of disease.'

The idea that considerable experience is needed to become a competent doctor fits various theoretical educational frameworks. Feedback, based on contacts with patients, is a central aspect of learning when looking at behavioural learning theories (Hattie & Timperley, 2007). Also, experiential learning, or learning from doing, is central to humanist, cognitive and social learning theories (Mann, 2011) and elaborated upon in Kolb’s experiential learning model (Kolb, 1984). In this model experiences are a central part of the learning cycle followed by reflection, abstract conceptualization and active experimentation. Studies showed that participation in meaningful, patient-related, activities is critical to the learning of (postgraduate) learners (Dornan et al, 2007; Teunissen et al, 2007).

According to Ericsson,(Ericsson, 2004) medical expertise develops by ‘deliberate practice’. He argues that expert performance is different from everyday performance, as it continues to improve as a function of more experience, coupled with deliberate practice. Expert performance is reached by actively acquiring and refining a cognitive mechanism to support continued learning and improvement. Becoming a medical expert thus requires engagement in practice and appropriate reflection, which can be stimulated by feedback from coaches or trainers (Ericsson, 2004). Based on this, Duvivier et al. recently described medical training programmes as developed to overcome weaknesses and to improve competence. The level of competence must be monitored to provide cues for further improvement. Deliberate practice based (medical) training is not the repetition of activities but a focused approach aiming for well-defined learning goals (Duvivier et al, 2011). Within this framework, patient mix is an important training condition because it embodies the
required representative tasks in the medical domain at issues onto which the desired competence can be practised. The patient mix offers different experiences on which reflection and assessment can be made by the trainee themself, by the trainer, or eventually, by an external preceptor.

In addition, other frameworks for medical expertise emphasize the importance of clinical experience for learning, such as theories of cognitive structures (Schmidt et al, 1990) and dual processing (Ark et al, 2007; Evans, 2007; Norman, 2009). The essence of these theories is that first conscious, intentional learning (deliberate practice) must be established before routines are automated. These automated routines are the basis of adequate medical handling (Pelaccia et al, 2011). Within these frameworks also, the experience needed is provided by an adequate patient mix, so patient mix is an important training condition. Well-supervised learners, exposed to an adequate patient mix can be assumed to substantially improve medical competence.

This review was carried out in order to evaluate whether this theory could also be confirmed by empirical evidence. Our primary aim was to systematically review research addressing the relationship between patient mix and learning in work-based clinical settings. Our secondary aim was to address the influence of additional variables (e.g. supervision and learning style) on this relationship.

**Definition of patient mix**

In order to obtain a view of the patient mix, a clear and workable definition of ‘patient mix’ has to be formulated. The first article with ‘patient mix’ in the title in Medline is a commentary by Edward Brandt Jr (Brandt E Jr, 1974) in 1974 on an article of McAllister and Dzur (McAllister, Jr. & Dzur, 1974) about the patient population in an acute medical care service. In this commentary, the author states that the ‘number of patients’ and the ‘types of medical problems’ are of prime importance and that clinical learning involves both quality and quantity. Numerous papers have been published reporting patient mix based on this ‘quality’ (diagnosis-diversity) and ‘quantity (patient-volume) approach (Hand et al, 1993; Raghoebbar-Krieger et al, 2001; Carney et al, 2002). In these papers, there is a large semantic overlap between the terms ‘clinical experience’, ‘clinical exposure’, ‘clinical encounters’ or ‘patient encounters’ and ‘case mix’ or ‘patient mix’. ‘Casemix’ in this respect might be a synonym to patient mix, but may also be used in broader context, for instance referring to the funding of the health care system.

‘Clinical exposure’ can be regarded as the umbrella term for clinical contacts of any kind. The term ‘patient mix’ inclines towards the description of the diversity of the exposure, focusing not only on variety or diversity, but also on quantity or volume. To measure patient mix, (‘case mix’ in the publication) a definition was formulated by Hutchinson ‘A system of
classifying ‘cases’ – patients, contacts, episodes, or visits – into groups which are similar according to some characteristic, such as diagnosis (e.g. International Classification of Diseases), treatment (e.g. OPCS operations codes), severity, potential for health-care improvements, or costliness (Hutchinson et al, 1991).’ Following Berlowitz, the major difference between a patient mix measure (case mix in the publication) and a classification system is in their application. Classification systems are developed to order patients into groups on the basis of their relationships. Patient mix measures intend to relate these groupings to an outcome. They may include a range of patient characteristics such as diagnoses, disease severity, gender, age, socioeconomic status, or functional status. Similarly, the outputs may reflect clinical status, resource utilization, cost, or learning outcome (Berlowitz et al, 1995).

This review focuses on patient mix and its relationship with learning. In order to maximise inclusion possibilities, a sensitive approach was chosen and therefore the original definition was used; the number of patients and the types of medical problems presented to learners (McAllister, Jr. & Dzur, 1974). Patient mix thus is regarded to consist of a number of patients presenting a certain diversity of diseases (Figure 1).

Figure 1. Patient mix model
Figure 1. Two-dimensional approach of patient mix. Consider a training programme in a large group of patients with the same diagnoses (A). Because there is no diversity, this cannot be considered to be a 'patient mix', but merely the training of a single skill or restricted clinical problem. Situation C expresses a situation in which a large diversity of skills and/or symptoms and diagnoses are theoretically possible, but very few or even no patients are present. This can be regarded as a patient mix, but an extremely meagre one – simply because there are no or very few patients. The line labelled ‘D’ expresses (an arbitrary) ‘cut-off point’ where the diversity is rich enough to start calling the population ‘patient mix’. All points labelled B are considered to be a patient mix.
Methods

Eligibility criteria (List 1)
As we aimed to assess the strength of the relationship between patient mix and learning, only studies reporting on quantitative data were included which were conducted with medical students/trainees at any level of the formal medical training/career. Patient mix volume, i.e. the quantity of patients encountered and the diversity of skills and/or symptoms and diagnoses had to be described. No simple cut-off for the width of this diversity could be given (Figure 1), but studies on the exposure to one restricted clinical problem or skill were excluded as they only described the volume of that skill or problem, and no diversity. Learning outcome had to be explicitly assessed. The relationship between patient mix and learning had to be quantified by statistical analysis.

Information sources and search strategy
The search was conducted across five sources relevant to education in a clinical context: Medline, Embase, Web of Science, ERIC and the Cochrane Library. The search ran from the start date of the database to July 2011 and was not limited by language, geography, or research methodology. The search strategy was composed by a clinical librarian. The search strategy had to be able to find a ‘reference set’ in PubMed. This set contained thirty-eight articles, previously rated as being relevant to the review subject by the authors. The strategy was then translated to the search systems of the other databases.

Study selection
Two authors (MW and JJ, or MV and JJ) individually and independently screened the titles and abstracts of all articles using the inclusion and exclusion criteria. Citations that were selected by one author but not by the other author were discussed in order to achieve negotiated consensus on inclusion or exclusion. In case of doubt or persisting disagreement in this phase, the article was included. The full text of all the potentially relevant articles was retrieved. The full-text articles were screened, again independently, by two authors, using the same criteria and were again compared. In case of disagreement, a decision on inclusion or exclusion was once more reached by negotiated consensus. Most studies that were excluded did not have an adequate description of patient mix or did not statistically address the relationship between patient mix and learning. At each screening phase, each citation was marked as ‘yes’, ‘maybe’ or ‘no’. Inter-observer agreement of the screening phase was measured by Cohen’s Kappa (linearly weighted). Manual searches were conducted across the citations of the papers that were coded, resulting in 17 more citations. These were screened by two authors, but none of them were included.
### List 1: Inclusion and exclusion criteria

**Inclusion criteria**

- Empirical, educational studies with actual patient exposure (no simulations), reporting on quantitative data.
- Study population: studies conducted with medical students/trainees at any level of the formal medical training/career.
- Patient mix, clinical encounters, or clinical experience in workplace-based learning had to be described. Patient mix had to be described in some detail, thereby addressing the volume as well as the diversity. Studies on the exposure to a restricted clinical problem or skill were excluded. Medical subspecialties were not excluded beforehand, as long as the patient mix was diverse.
- Learning outcome measures had to be described by self-reported measures, assessment by trainers, preceptors, or others, or by objective structured clinical examinations (OSCEs) either with real or with standardized patients, multiple choice, or other written exercises.
- The relationship between patient mix and learning had to be quantified by statistical analysis.
- Studies in all languages were included.

**Exclusion criteria**

- Studies on qualitative research.
- Dental and veterinary curricula, any paramedical curricula, nursing curricula, physician assistant curricula, nurse practitioner curricula, dietetic curricula.
- Theoretical medical curricula (not work-based).
- Complementary/alternative medicine.

**Patient Mix Operationalisations**

- Volumes of patient encounters
- 'Top 10' Encounters per organ systems specified
- Encounters per specialism specified
- Encounters per predefined skills
- Content of the course/rotation/apprenticeship
- Encounters per diagnosis

**Learning outcomes Content**

- Theoretical knowledge (Specify)
- Specific Technical Skills (id)
- Clinical competence in practice (id)
**Data extraction**

A detailed data extraction form was developed using the Best Evidence in Medical Education (BEME) standard coding sheet and published reviews (Steinert et al., 2006; Colthart et al., 2008; BEME, 2012) as a basis. All selected papers were coded by the authors in pairs (MW and JJ, or MV and JJ). This form contained a general description of the study design and participants, including the training level and the specialist training area (appendix 2). In addition, patient mix instruments (e.g. electronic logbooks and questionnaires), volume/diversity descriptions (e.g. top 10 skills or diagnoses lists), learning outcome measures, and the relationship found between patient mix and learning were recorded (Table 2). We also documented the highest level of the Kirkpatrick hierarchy (Kirkpatrick & Kirkpatrick, 2006) on which learning outcomes were assessed. If additional variables were studied in relation to learning outcome (e.g. learning style and supervision), these were also recorded.

**Quality of the studies**

To obtain an overview of the quality of the included studies, and thereby the validity of the outcomes, we assessed them with the recently developed Medical Education Research Study Quality Instrument (MERSQI) (Reed et al., 2007). This instrument was chosen because, to our knowledge, it is the only instrument fitted to measure the quality of experimental, quasi-experimental, and considering medical education. The maximum total MERSQI score is 18. Two authors (JJ and MV) independently scored the quality of the included papers. In case of disagreement on item scores, a decision was reached by negotiated consensus.

**Data analyses**

The various ways in which patient mix was operationalized were categorized in equivalent approaches of volume and diversity descriptions. Learning outcomes were divided into self-reported outcomes and outcomes using formal assessments. The relationship between patient mix and learning is described in sections based on different learning outcomes, as this allowed for homogeneous reporting of results.
Results

Search results
The search resulted in 11,098 titles. After removal of duplicates, 10,420 studies were reviewed based on title and abstract. Of these studies, 298 were identified as potentially relevant and included for full-text analysis, which resulted in the inclusion of 22 papers (Figure 2). The studies identified had insufficient homogeneous or quantitative data to allow meta-analysis or other formal synthesis. During screening of titles and abstracts, the inter-observer agreement kappa (linearly weighted) was 0.34 (MV–JJ) respectively 0.32 (MW–JJ).

Table 2 provides a summary of study descriptions and outcomes. This table forms the basis for the inferences from the studies in the following paragraphs.

**Phase 1**

**Phase 2**

**Phase 3**

**Phase 4**
Methodological quality of studies
MERQI sum-scores ranged from 8.0 to 14.5 (median 11.75). Ten studies reported on the internal structure of their outcome instruments by Cronbach’s Alpha (Table 2) or principal component analysis. Response rates, if presented, varied from 43% to 100%. Data analyses were appropriate in all but one study (Martin et al, 2000) and all were beyond the descriptive level. Four studies reported outcome only at student reaction Kirkpatrick level 1 (Dolmans et al, 2002; O’Hara et al, 2002; Saywell et al, 2002; van der Zwet et al, 2010) whereas 10 studies measured knowledge and/or skills (Kirkpatrick 2) (Gruppen et al, 1993; Schwiebert et al, 1993; McLeod et al, 1997; Jacobson et al, 1998; Greenberg & Getson, 1999; Boots et al, 2008; Lampe et al, 2008; Nomura et al, 2008; Duke et al, 2011; Yu et al, 2011). Less than half of the studies (n=8) measured outcomes up to the behavioural level (Kirkpatrick 3) (Chatenay et al, 1996; Jolly et al, 1996; McManus et al, 1998; Ahmed & Hughes, 1999; Martin et al, 2000; Sorensen et al, 2004; Wimmers et al, 2006a; Fung et al, 2007). None of the included studies explicitly measured patient or health-care outcome (Kirkpatrick 4).

Types of studies
In six studies, the mutual dependence of factors related to learning was addressed in a path analysis or structural equation modelling (SEM) (Jolly et al, 1996; Martin et al, 2000; Dolmans et al, 2002; Sorensen et al, 2004; Wimmers et al, 2006a; van der Zwet et al, 2010) (Table 2). Eight studies compared the patient mix of training sites and their contribution to learning. In three of these studies, similar sites were compared, (Chatenay et al, 1996; Wimmers et al, 2006a; Yu et al, 2011) three others compared academic vs. non-academic sites (Schwiebert et al, 1993; McLeod et al, 1997; Nomura et al, 2008) and two compared inpatients and outpatients (Jacobson et al, 1998; Duke et al, 2011).

Four studies evaluated the learning effects of an intervention: the introduction of a rotation (Gruppen et al, 1993), a skill-training programme (Boots et al, 2008), identification of 10 preselected complaints (Lampe et al, 2008) and a new internship (Nomura et al, 2008). Two studies compared groups of medical students at a different phase of their training (Ahmed & Hughes, 1999; Boots et al, 2008). In four studies, the groups and sites were homogeneous and no interventions were studied (McManus et al, 1998; O’Hara et al, 2002; Saywell et al, 2002; Fung et al, 2007).

Operationalization of patient mix
Patient mix, or any other term intended to describe the exposure of students/trainees at any level, to patients with health problems, was in none of the studies explicitly defined. The terms (clinical) exposure, experiences, encounters or content are used, as are student or learning experiences and of course patient mix. Patient mix was measured with various
instruments (see Table 1 and 2), including questionnaires (n=11), interviews (n=1), and logbooks (n=13), the latter hand-written (n=9), electronic (n=2), or unspecified (n=2). Patient mix was mostly described as the variety of encountered skills and/or diagnoses. Skills were usually technical procedures, such as intubation (Boots et al, 2008) or suturing (Jolly et al, 1996). In some studies (n=6), the patient volume was the most pronounced patient mix characteristic (Schwiebert et al, 1993; Jolly et al, 1996; Greenberg & Getson, 1999; Martin et al, 2000; Dolmans et al, 2002; van der Zwet et al, 2010). The diversity of the patient mix in these studies was often additionally addressed by one or two variables, but the reports lacked a detailed insight into the diversity of diagnoses.

In most other studies, the distribution of encountered diagnoses and medical skills was presented. Several authors presented a top 10 or 20 of the conditions the students meet most frequently (Schwiebert et al, 1993; McLeod et al, 1997; Jacobson et al, 1998; Saywell et al, 2002). This method was also used to compare the patient mix of different sites.

**Operationalization of learning**

Learning outcome measures can be divided into self-reported outcomes and formal assessments. Self-reported outcomes are used in ten studies, in five of these, (O’Hara et al, 2002; Saywell et al, 2002; Boots et al, 2008; Nomura et al, 2008; Duke et al, 2011) the self-estimated competence was measured as self-confidence (Boots et al, 2008; Nomura et al, 2008; Duke et al, 2011) or comfort level (Schwiebert et al, 1993; Saywell et al, 2002). In the five other studies, the quality of the learning experience or the educational profit of the experience at issue is asked for; such as the effectiveness, the learning benefit, or instructional quality of the rotation (McLeod et al, 1997; Jacobson et al, 1998; Dolmans et al, 2002; Sorensen et al, 2004; van der Zwet et al, 2010).

**Relationship between patient mix and learning**

The relationship between patient mix and learning was tested in two different manners:
1. By comparing learning outcomes between existing groups of learners (e.g. cohorts) with patient mix described at the group level

2. By relating patient mix indices at the level of the individual learner to a learning outcome. (Table 2).

**Outcomes based on self-reporting**

Out of ten studies, four found a positive relationship between patient mix and self-reported outcomes evaluating the progress in competence as experienced by the students or residents, such as self-confidence and comfort level (O'Hara et al, 2002; Saywell et al, 2002; Boots et al, 2008; Nomura et al, 2008). By contrast, one study found no difference in confidence between residents in a traditional inpatient rotation and a new one in which experience in ambulatory settings was introduced (Duke et al, 2011).

Patient mix was also found to correlate with self-reported outcomes evaluating the quality of the learning period, such as self-reported learning benefit, experienced effectiveness of the rotation, or the instructional quality (McLeod et al, 1997; Jacobson et al, 1998; Dolmans et al, 2002; Sorensen et al, 2004; van der Zwet et al, 2010).

**Outcomes based on formal assessment**

**MCQ or other written examinations**

In one trial of the eight studies using MCQ and/or written examinations, students in an intervention group who encountered significantly more often patients with 10 chief prerequisite complaints than the control group (31.8% vs 6%) outperformed the control group on a general knowledge examination ($p=0.014$) (Lampe et al, 2008). In seven other studies, however, no relationship between patient mix and scores on MCQs or other written examinations was found (Gruppen et al, 1993; Schwiebert et al, 1993; Chatenay et al, 1996; McManus et al, 1998; Ahmed & Hughes, 1999; Greenberg & Getson, 1999; Duke et al, 2011).

**OSCE**

No association was found between patient mix and performance in four of the five studies using OSCE assessment (Chatenay et al, 1996; Jolly et al, 1996; Martin et al, 2000; Fung et al, 2007; Yu et al, 2011). Fung et al. suggested that the time allotted for students to complete clerkships may not be sufficient to expose them to the number of patients needed to
generate a significant effect on clinical performance (Fung et al, 2007). In one study, the OSCE scores even seemed lower in students who attended a higher number of outpatient clinics than those attending fewer outpatient clinics, although experience with emergency admissions and obtaining feedback on these seemed to improve OSCE performance (Chatenay et al, 1996). The authors concluded that the clinical skills were enhanced by an increased volume of some, but not all, clinical experience. Jolly et al. found that students scored higher on OSCEs if they examined patients on their own, if the objectives (presumably the objectives of the rotation, not reported) had been made clear, and a higher number of clinics were attended (Jolly et al, 1996).

**Oral examinations**

In the two studies using oral examinations, no relation between patient mix and students’ examination scores was found (Schwiebert et al, 1993; Wimmers et al, 2006b).

**Clinical assessments**

Wimmers et al. found that an increased number of patient encounters did not directly lead to improved clinical performance as assessed by supervisors in 227 medical students, (Wimmers et al, 2006a) as was the case in two other studies out of six studies using clinical assessments (Chatenay et al, 1996; McManus et al, 1998). They did, however, find a strong relationship between number of patients and number of diseases encountered (r=0.89) (Wimmers et al, 2006a). Ahmed and Hughes, in contrast, found that students’ exposure rates did correlate with the assessment grades awarded by clinical supervisors, but not with a written exercise (quiz) score (Ahmed & Hughes, 1999). Also Greenberg and Getson found a weak positive correlation between number of patients seen and the students’ clinical performance (Greenberg & Getson, 1999).

**Variables potentially relevant to the relationship between patient mix and learning**

Martin et al. found that students with a deep, strategic, and well-organized learning style reported significantly higher clinical exposure (combined score for three areas of clinical activity). The well-organized style was also associated with OSCE performance (Martin et al, 2000). McManus et al. additionally found that the amount of knowledge students gained from clinical experience was related to strategic and deep learning styles (McManus et al, 1998) as was success in a final examination: positive and significant correlations were found for deep and strategic learning, whereas surface learning correlated negatively.

In the path analysis presented by Wimmers et al., supervision quality loaded on patient mix volume and on clinical competence (Wimmers et al, 2006a). Hoifoidt et al., however, did not find supervision to load on patient mix volume or on (subjective) learning.
benefit (Sorensen et al, 2004) while in the model of Van der Zwet et al., supervision loaded on both patient mix and instructional quality (van der Zwet et al, 2010). In the study by Dolmans et al., a relationship was found between supervision and the effectiveness of a rotation (Dolmans et al, 2002). Also, a significant two-way interaction was found between patient mix and supervision; the latter more strongly influenced the effectiveness of the rotation than patient mix did. In another study, OSCE score also seemed to be ‘modified’ by the quality of the feedback (Chatenay et al, 1996).

Hoifoidt et al. described that the amount of experience of pre-registration house officers, on 12 different psychiatric areas correlated with the quality of the learning environment which itself was related to the learning benefit (Sorensen et al, 2004).

In the study by Yu et al., the overall quality of the surgical clerkship, as perceived by students, was related to the number of cases seen, although no difference in learning outcome was found (Yu et al, 2011). Jolly et al. found that six of 43 questionnaire variables correlated with OSCE score. Two of these six can be considered to be related to the learning climate, namely ‘whether students examined patients on their own’ and ‘whether objectives were made clear’ (Jolly et al, 1996).
Discussion

In most studies dealing with the relationship between patient mix and student self-assessment (self-confidence, comfort level), indications of a relationship were found. The indications of positive relationships were stronger regarding the quality of the learning experience (learning benefit, instructional quality, or effectiveness of a rotation). Supervision quality seems to be a mediating factor, which was repetitively found to improve patient- or education-related outcome (Farnan et al, 2012). This can be regarded to be consistent with the theory of deliberate practice.

The relationship between patient mix and learning outcome was not corroborated with formal assessment outcomes. All but one study dealing with MCQ or other written examinations failed to find any relationship between patient mix and MCQ or written examinations. All the studies relating patient mix to OSCE score found no association, or under some conditions even a negative association (Chatenay et al, 1996). In one study, (Ahmed & Hughes, 1999) a correlation was found between exposure rate and clinical assessment grades, whereas three other studies did not find such a relationship (Gruppen et al, 1993; McManus et al, 1998; Wimmers et al, 2006a).

The patient mix (also called ‘clinical exposure’ or ‘case mix’) in the articles we reviewed was mostly presented without definition. We found studies describing skills, diagnoses, treatments, or general ideas about patient mix, within different specialties and measured by logbook or questionnaires and presented differently, making the patient mix descriptions extremely heterogeneous. The heterogeneity we found is particularly interesting. In the light of the emphasis, adequate patient mix has gained in the diverse accreditation standards of several countries (Liaison Committee on Medical Education (LCME), 2011; Royal College of General Practitioners, 2011) and internationally (Karle, 2010). Due to the heterogeneity, we had difficulty in finding a proper cut-off point for the number of diagnoses or skills that need to be engaged to fulfil the diversity inclusion criterion. This heterogeneity indicates the need for a discussion on the value of the concept. Berlowitz et al. stated that patient mix should describe how patients are distributed along characteristics that may affect specific outcomes of interest (Berlowitz et al, 1995); he thereby stresses that the concept of patient mix in itself is not relevant. The fact that the patient mixes described in the reviewed studies are so diverse, may be partly because they are related to different outcomes in the different settings at different stages of education. It often seemed that the presented patient mix depended on the instrument the authors had to their disposal and not on study-specific operationalization of the desired patient mix of the attachment. Following Berlowitz, Patient mix descriptions should primarily be based on the desired learning outcomes.

An example of a suitable description of the patient mix is found in the study of Gruppen et al. In this study the patient contact numbers of students are reported for a vast number (>20) of
conditions, as are proportions and frequency orders (‘top 10’). In this study students had contact with at least one patient of 61 conditions reported in quartile ranges. The change in knowledge (pre-post test design) is displayed for 14 conditions, as is an overall score.

Besides the relationship with the outcome, more clarity about the relationship between the diversity and volume aspects of patient mix might be strived for. In this review, we found operationalizations of patient mix that were fairly different in that respect, allowing for very few inferences between studies.

The learning outcome measures were classified into self-reported assessment and formal assessment. The precise description of the used formal assessment methods in the studies was often meagre; example questions or exercises were not found. The reliability of clinical assessments is questionable; subjectivity can be a problem. Pulito et al. found that direct observations of trainees interacting with patients occur too infrequently (Pulito et al., 2006). Students prepare for assessments and their results may reflect their preparation more than their real competence (Al-Kadri et al., 2012). Terms such as OSCE or MCQ might suggest that similar instruments were used in different studies. However, the precise content and the number of stations or questions were found to differ, if mentioned at all.

We formulated six possible explanations that could explain why we found so little evidence for the relationship between patient mix and the results of formal assessment.

1. **Patient mix does not contribute to medical competence development.**

   This idea is highly unlikely, although theoretically possible. The positive relationship between patient mix and self-assessment outcome (compared with formal assessment) is not per se an indication of a relationship between patient mix and learning. Self–assessments have many limitations, as is discussed in several reviews, all concluding that self-assessment has little validity and reliability (Jocelyn et al, 1997; Eva & Regehr, 2005; Davis DA, 2006; Sargeant et al, 2008; Colthart et al, 2008). Poor performers were found to overestimate their competence (Kruger & Dunning, 1999; Fidler et al, 1999; Violato & Lockyer, 2006). The largely absent relationship between patient mix and formal assessment might indicate that ‘clinical experience without training increases confidence but not competence’ (Marteau et al, 1990; Bulstrode & Holsgrove, 1996; McManus et al, 1998). The idea that one becomes automatically more competent with increasing experience can be illusory. One of the causes for the absence of relationship might be ‘arrested development’. Many of our skills stop to improve once we reach a certain level of competence and a sufficient level of mastery is accepted) (Ericsson, 2004).
2. The relationship between patient mix and learning is more complex and many other variables play a role (such as supervision quality, learning style, learning environment, or professionalism).

Based on deliberate practice and other educational theories, like social learning theory (Bandura, 2006) and motivational theories, the importance of other variables in the relationship could be expected. Medical expertise develops by focusing on learning goals and by identifying areas for improvement. Patient mix provides the repetitive tasks needed for deliberate practice. To guide their learning, students also need supervision from preceptors. In several studies, supervision was found to be strongly related to learning outcome (Dolmans et al, 2002; Wimmers et al, 2006a; van der Zwet et al, 2010). It may, therefore, be seen as an important mediator. Supervision quality was, however, not described or measured in the majority of the included studies, and the potentially mediating effect may have been overlooked. This may have been the case with other variables related to learning as well.

3. The time span covered in most studies was too short.

Current educational theories assume a general problem-solving ability, but case-specific competences is considered of predominant importance (Wimmers et al, 2007). This means that competences does not transfer easily, (Patel & Cranton, 1983; van der Vleuten & Swanson, 1990) implying that exposure in many domains and in many different situations is essential for doctors to become fully competent. This takes time. The time-span covered by most of the included studies, may have been too short to find positive results.

4. The patient mix is inadequately measured.

Patient mix is usually described by encountered skills or diagnoses and in terms of volume and diversity. Other potentially relevant descriptors are the complexity in relation to the stage of learning and the learning value or benefit of cases. These aspects, with exceptions, are not usually described, so the validity of the instruments might have been imperfect. To what extent the reported patient mix represents the repetitive tasks needed for deliberate practice was never explicitly described in the studies we included.

Furthermore, in several studies, the patient mix was aggregated per training site and comparison was made between sites, not between students. Maybe this is a too coarse comparison to establish the relationship between patient mix and learning which can also be regarded as a limitation of our inclusion and exclusion criteria.

5. The validity of formal assessment is insufficient.
In a systematic review, Hamdy et al. found only mild to moderate correlations between measurements obtained in medical schools and future performance in medical practice (Hamdy et al., 2006). McManus also questioned the clinical validity of OSCEs. (McManus et al., 1998) OSCEs, MCQs and other assessments may not be appropriate for determining the specific contribution of patient mix on learning.

Self-reported outcome instruments are usually designed especially for the study, whereas the formal assessments used are commonly part of the standard assessment procedures. These standard assessments are not tailored to the study question and may suffer from bias due to the preparation of students for assessments (Newble & Jaeger, 1983). Self-report instruments might therefore be a more appropriate fit for the research questions.

6. The quality of the studies was insufficient.

The majority of the included studies had a single-group, post-test-only design which may be considered inferior to pre–post test designs \((n=4)\) or trials \((n=2)\). Several studies were merely a comparison of training sites or an evaluation of a new curriculum (Ahmed & Hughes, 1999; Nomura et al., 2008).

Limitations

Composing an efficient and sufficient search strategy is complex. Despite our attempts to sharpen the patient mix definition to an accurate and workable one, we made pragmatic choices. We were not able to formulate the exact border between ‘some disease (or skills)’ and ‘patient mix’. This resulted in a low inter-rater agreement. A substantial number of papers were included or excluded based on negotiated consensus. This happened more in the beginning of the review process (Phases 1–3) than later (Phase 4). A minority of the studies included were intended to specifically explore the relationship between patient mix and learning for general educational theory purposes. Most of the studies concerned merely an evaluation of a programme or curriculum change, or were a comparison between training sites. Many studies had to be excluded because they lacked a statistical analysis of the relationship between patient mix and learning outcome.

Future directions

The volume increase in students and junior doctors may lead to problems with training due to restrictions in clinical interactions. We need to be aware of the likely effects of this increase and what the minimal (or optimal) case load, hours and supervision time is needed, to enable, or optimize adequate training at each learning level. This systematic review emphasizes the problem with the description of ‘patient mix’. Despite its attention in
international accreditation standards, the concept itself seems poorly defined. Educational research would benefit from a standardized approach in patient mix descriptions; volume can always be measured, but diversity should be explicated in relation to the outcome. A model for patient mix measurement is suggested in figure 3.

Figure 3: model for reporting patient mix

Learning aims

-> explicitation, operationalisation by assessment

↓

‘Adequate’ patient mix:
- **Diversity**: i.e. diagnoses, complexity, age, gender, ethnicity, continuity/follow up
- **Volume**: descriptions for each diversity item
  + absolute, percentages, top 10/20, explicit which learners had relatively low/high exposure

In this figure, a model for the description of patient mix is proposed. The reported patient mix should be based on the learning aims of the learners in an attachment. An adequate patient mix is based on the learning aims. Depending on the learning aims patient mix diversity is operationalized in terms of diagnoses age, gender, ethnicity, complexity of the cases, continuity/follow up, or other relevant aspects. The volume that is going along with the different values of the diversity should be reported in both absolute and proportional figures. Frequency sorting (top 10/20) is also recommended, as is reporting of the proportion of the learners that had a relatively high or low exposure.

Future studies should aim at addressing which parts of patient mix contribute to learning and which parts do not. A theoretical framework accounting for other relevant parameters in the relationship between patient mix and learning, such as supervision and learning style, may be helpful, and instead of using the standard assessment procedures, objective outcome tailored to the research question should be developed.

Nearly all studies at hand ‘accepted’ the patient mix that was presented to the participants as a given factor. Interventions on the patient mix were indirect (curriculum change) active influencing of the patient mix was not found. It would be interesting to see what the effect of tailoring the patient mix to the specific learning goals and needs of individual students would yield.
To avoid bias due to preparation for an examination, research question tailored study outcome (assessments) should be unobtrusive; (Swanson et al, 2012) for instance, assessments based on a random selection of routinely made video recordings (Ram et al, 1999; Freeman, 2007) could be considered as can frequent work-based assessments by different preceptors. If, at second best, a traditional approach is chosen – similar to the designs we found, triangulation should be strived for. This can be reached by measuring study-tailored self-assessment, including the quality of the learning experience and self-confidence or alike, combined with formal assessment derived from knowledge assessment, and assessment of clinical competence. These studies are preferably done in multi-institution trials.

In a systematic review, Colthart et al. found indications that “skills may be better self-assessed than knowledge” and “the accuracy of self-assessment may be enhanced by increasing the learner’s awareness of the standard to be achieved” (Colthart et al, 2008). This is specifically mentioned here, because initially, a medical student may need focused feedback from supervisors, however as they progress they should become lifelong learners and must develop the ability to self-assess (Duvivier et al, 2011)

An inquiry into the detailed aspects of patient mix, and the contribution of these aspects to learning is desirable. This may be done in qualitative studies; trainees and clinical teachers may be interviewed about their ideas of minimal or optimal patient volumes and spread of diagnosis diversity and their benefit for learning.

The MERSQI in our experience is a promising, easy usable instrument for assessing the quality of educational studies. However, some annotations must be made. Several MERSQI items were multi-interpretable, like study design, number of institutions or response rate. Other items, like content and appropriateness of the analysis, did not discriminate between the studies we included. Based on the MERSQI sores, one gets an impression of the spread in quality between the studies. Since the experience with the MERSQI is limited, it does not seem advisable yet to use a cut-off score for excluding low quality studies.

Conclusions
In the studies we reviewed, patient mix is mostly presented without definition. Based on our set of studies, we found indications that patient mix, defined by us in terms of volume and diversity, is related to self-reported learning outcome, most evidently the experienced quality of the learning programme. A relationship between patient mix and the results of formal assessment has rarely been demonstrated. Not only supervision in particular, but also learning style seem mediating variables of the relationship between patient mix and learning.
